

**INTRODUCTION**

The Gila Valley sub-basin of the Safford basin is located in southeastern Arizona and encompasses approximately 1,642 square miles. The mountains that bound the sub-basin are the Gila on the northeast, the Pinaleno on the east and the Pinaleno and Santa Teresa on the southwest. An arbitrary line 5 miles downstream from the town of Geronimo forms the northeast boundary, and a ridge line south of Tanque marks the southeast boundary. The principal drainage for the Gila Valley sub-basin is the Gila River which enters the valley in the east and exits to the northwest. The San Simon River drains the southern part of the sub-basin and then converges with the Gila River. The major communities are Safford, Thatcher, and Pinal; at least a dozen smaller communities dot the Gila Valley sub-basin. The major industry is farming and in 1988, about 40,000 acres were irrigated (Norman Norton, Agricultural Stabilization and Conservation Service, oral comm., 1990). The primary crops are cotton and alfalfa.

Climate in the Gila Valley sub-basin is semiarid and warm. Precipitation is about 9 inches per year in the inner valley, greater than 30 inches per year in the surrounding mountains (Witcher, 1982, p. 1), and occurs mostly during July, August, and September. The average maximum daily temperature is about 104°F in July and about 69°F in January, while the average minimum daily temperature is about 69°F in July and about 29°F in January. An extreme high temperature of 116°F in June 1971, and an extreme low temperature of 6°F in January 1910, have been recorded (Sellers and others, 1985, p. 89, 92, 101, 104, 114).

Before 1920 the native vegetation was creosote (a xerophyte) on the slopes, and cottonwood, willow, baccharis, and mesquite (phreatophytes) on the bottom land (Gatewood and others, 1950, p. 9). Salt cedar (a phreatophyte) has now taken over much of the bottom land that is not cleared for irrigation. Early settlers in the sub-basin began irrigation of crops around 1872 by diverting flow of the Gila River (Turner and others, 1946, p. 2). Drought and an increase of cultivated land in the mid 1930's resulted in demands for water in excess of surface-water supplies, and prompted the drilling of water wells to provide a supplemental and more dependable source of water. In 1989, the most recent year for which data are available, approximately 71,000 acre-feet of groundwater was pumped in the Gila Valley sub-basin (Alice Knechtel, U.S. Geological Survey, oral comm., 1990). Diversions of surface water from the main stem of the Gila River in the Gila Valley sub-basin are administered by the Gila Water Commissioner in Safford, Arizona, pursuant to the Globe Order, Number 59 Decree. In 1989, approximately 138,000 acre-feet was diverted.

**GEOLOGY**

The Gila Valley sub-basin is part of a large, sediment-filled, trough-like depression typical of the geologic structures of the Mexican Highland section of the Basin and Range physiographic province. Halpern and Cushman (1947, p. 3) divided the basin fill into two units—the younger alluvial fill and the older alluvial fill. The deposits of the younger alluvial fill are of fluvial origin. This unit, rarely wider than 4 miles, consists of clay and unconsolidated silt, sand, and gravel, which all occur in discontinuous lenticular beds. The unit is thickest near Safford and Thatcher where it averages about 85 feet; near Geronimo it thins to about 30 feet. A discontinuous blue clay bottom is present in only a few places in the older alluvial fill, which is more or less consolidated. The major part of the structural trough which forms the Gila Valley sub-basin is the older alluvial fill and can be divided into three facies. In descending order they are a clay-silt facies, evaporite facies, and basal-conglomerate facies (Harbour, 1966, p. 23). The clay-silt facies, believed to be lacustrine in origin, is noted in a drifter's log to be as much as 610 feet thick (Knechtel, 1938, p. 202). The evaporite facies, as described by Harbour (1966, p. 24), consists of salt beds, gypsum, limestone, and apatiferous clay and shale. This facies is the thickest near the basin axis and thins laterally with the clay-silt facies (Harbour, 1966, p. 34). According to Harbour (1966, p. 24), the basal-conglomerate facies extends basin-wide under the clay-silt and evaporite facies. This basal-conglomerate facies is nonindurated to moderately indurated sand and gravel, and is interbedded with the clay-silt facies near the town of Thatcher (Witcher, 1982, p. 1). Gravity modeling shows that the older alluvial fill is very thick. In an area a few miles southwest of Safford, sediments may be as much as 11,200 feet thick. In most of the sub-basin sediments are inferred to be thicker than 4,000 feet (Oppenheimer, 1980). At least one well has been drilled to a depth of 3,767 feet without encountering bedrock.

**OCCURRENCE AND MOVEMENT OF GROUNDWATER**

Groundwater in the Gila Valley sub-basin occurs in both the younger alluvial fill and the underlying older alluvial fill. Water-level data, in conjunction with limited numbers of drifter's logs and associated construction data, indicate that both alluvial units likely function as a single aquifer system. Water-level elevation contours on map 1 reflect this assumption. In general, groundwater flows from the basin margins toward the axis of the valley, then the flow is northwest, parallel to the Gila River. Although the bulk of the retrievable groundwater is in the older alluvial fill, the younger alluvial fill is the unit of principal use. Due to the lenticular character of the younger alluvial fill, groundwater is often encountered at different levels in the same location. Well discharges of up to 2,500 gallons per minute (gal/min) have been reported, but the average seems to be about 1,000 gal/min.

In 1989, the most recent year for which data are available, approximately 71,000 acre-feet of groundwater was pumped in the Gila Valley sub-basin (Alice Knechtel, U.S. Geological Survey, oral comm., 1990). Diversions of surface water from the main stem of the Gila River in the Gila Valley sub-basin are administered by the Gila Water Commissioner in Safford, Arizona, pursuant to the Globe Order, Number 59 Decree. In 1989, approximately 138,000 acre-feet was diverted.

Within the older alluvial fill, the clay-silt facies restricts the vertical movement of groundwater in the underlying basal-conglomerate facies, causing artesian conditions that result in some artesian wells. The highly mineralized groundwater recovered from some wells completed in the older alluvial fill is probably a consequence of the deposits in the evaporite facies. Drifter's logs of wells near Arizota that penetrate the conglomerate facies show an interbedding of clay and conglomerate. This interbedding creates an aquifer system with the characteristics of fingers that are hydrologically connected. Discharges up to 660 gal/min from irrigation wells near Arizota have been reported by well driller's log entries in the basin, warm or hot water up to 46°C obtained from some wells and springs may have come from a great depth through fractures in the older alluvial fill caused by faulting (Turner and others, 1946, p. 6).

The Gila River is the primary source of recharge to the Gila Valley sub-basin and rapid water-level rises in response to surface-water flow are observed in wells completed along the Gila River. In addition, mountain-front recharge occurs in stream channels that have cut into caliche-capped gravel zones along the Pinaleno Mountains. This supplies a considerable amount of groundwater to the sub-basin. Witcher (1982, p. 23) suggests that recharge occurs in fractures along basement fault zones in the Pinaleno Mountains. Other recharge sources are seepage from canals and deep percolation from irrigation. Underflow from the adjacent San Simon sub-basin also recharges the Gila Valley sub-basin. Precipitation in the inner valley is not a substantial source of recharge.

**WATER QUALITY**

Groundwater from the younger alluvial fill in the Gila Valley sub-basin is generally suitable for irrigation, and unsuitable without treatment for public consumption, due to high concentrations of dissolved solids and fluoride. There are two factors that contribute to these high concentrations. The first is groundwater seepage from the older alluvial fill into the younger alluvial fill, as indicated by localized unusually high dissolved-solids concentrations in the younger alluvial fill. Much of the dissolved solids are specifically derived from the evaporite facies in the older alluvial fill. The second is seepage from irrigation canals and infiltration of irrigation return water into the younger alluvial fill. The sodium-adsorption ratio values are mostly in the medium to low range in waters derived from the younger alluvial fill, indicating medium to low sodium hazard for irrigation. The sodium-adsorption ratio is an indicator of the potential for irrigation water and soil to enter cation exchange with sodium from the water tending to replace adsorbed calcium and magnesium in the soil. Water with a high sodium adsorption ratio may increase the difficulty of cultivating the soil. Water quality in the older alluvial fill is poor in the central part of the basin, but appears to improve along the mountain front near Arizota possibly due to the absence of the evaporite facies there. The sodium-adsorption ratios are in the high range in most of the older alluvial fill. The range of fluoride values in the older alluvial fill was 0.4 mg/L to 16.2 mg/L. The range of fluoride values in the younger alluvial fill was 0.6 mg/L to 3.8 mg/L.

The maximum contaminant level (MCL) for fluoride in public drinking-water supplies, as recommended by the U.S. Environmental Protection Agency and the Arizona Department of Environmental Quality, is 4.0 milligrams per liter (mg/L). There were 108 water samples collected in the sub-basin between 1985 and 1990, and more than a third exceeded the MCL for fluoride. All of the samples exceeding the MCL were from wells completed in the older alluvial fill. The range of fluoride values in the older alluvial fill was 0.4 mg/L to 16.2 mg/L. The range of fluoride values in the younger alluvial fill was 0.6 mg/L to 3.8 mg/L.

Dissolved-solids concentration may be approximated by multiplying specific-conductance values by 0.6, which is the approximate ratio of dissolved solids in mg/L to specific conductance in microsiemens per centimeter (µS/cm). The U.S. Environmental Protection Agency's secondary standards for drinking water has a MCL of 500 mg/L (500 µS/cm) for dissolved solids. The range of specific-conductance values was 65 to 27,700 µS/cm and 82 of the 108 samples exceeded the MCL for dissolved solids. Most of the samples that did not exceed the limit were collected from wells in younger alluvial fill along tributaries of the Gila River and from springs on the southern side of the basin. Water with dissolved-solids concentration exceeding 1,000 mg/L (1,067 µS/cm) may have adverse effects on many crops and may cause physiological effects on humans and animals (U.S. Environmental Protection Agency, 1986a). The dissolved-solids concentration of 1,000 mg/L was exceeded in 54 of the 108 wells and springs that were sampled in both the older and younger alluvial fill.

Elevated arsenic levels that exceed the MCL of 50 µg/L for arsenic have been noted in samples obtained from six wells (table 2). Four of the wells are completed in the older alluvial fill. The other two lack construction data but it is assumed that they are also completed in the older alluvial fill.

**EXPLANATION**

WELL IN YOUNGER ALLUVIAL FILL FROM WHICH A WATER SAMPLE WAS COLLECTED IN 1985-90—First number, 2100, is specific conductance in microsiemens per centimeter at 25°C (specific conductance is an indication of the dissolved-solids concentration in water). Second number, 3.8, is the fluoride concentration in milligrams per liter.

WELL IN OLDER ALLUVIAL FILL FROM WHICH A WATER SAMPLE WAS COLLECTED IN 1985-90—First number, 1700, is specific conductance in microsiemens per centimeter at 25°C (specific conductance is an indication of the dissolved-solids concentration in water). Second number, 1.3, is the fluoride concentration in milligrams per liter.

SPRING FOR WHICH A WATER SAMPLE WAS COLLECTED IN 1985-90—First number, 800, is specific conductance in microsiemens per centimeter at 25°C (specific conductance is an indication of the dissolved-solids concentration in water). Second number, 1.3, is the fluoride concentration in milligrams per liter.

WELL IN YOUNGER ALLUVIAL FILL FOR WHICH A HYDROGRAPH DEPICTING CHANGES IN DEPTH TO WATER IS SHOWN

WELL IN OLDER ALLUVIAL FILL FOR WHICH A HYDROGRAPH DEPICTING CHANGES IN DEPTH TO WATER IS SHOWN

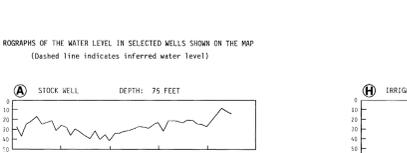

BEDROCK (VOLCANIC, GRANITIC, OR METAMORPHIC)—Water may occur in weathered or fractured zones, joint systems, or thin veneer of alluvial or fluvial deposits overlying bedrock.

ALLUVIAL-FILL DEPOSITS (CONSIST OF SILT, SAND, CLAY, GRAVEL, AND CONGLOMERATE)

WATER-LEVEL CONTOUR—Shows approximate altitude of the water level. Contour interval 50 and 100 feet, datum is mean sea level, dashed where inferred.

GILA VALLEY SUB-BASIN BOUNDARY

**CHEMICAL QUALITY DIAGRAM**—Shows major constituents in milliequivalents per liter. The diagrams are in a variety of shapes and sizes, providing a means of comparing, correcting, and characterizing water in different types of water. 1985, below diagram, indicates year in which sample was collected.

**ROGHOGRAPHS OF THE WATER LEVEL IN SELECTED WELLS SHOWN ON THE MAP**
